Most programs interact with a user. A program might need to say something to a user, that is, print something on a screen (output). To this end, we can use the function print that we saw last week. Also, the user might need to say something to the program (input). To this end, we use the function input():

```python
variable = input() # the program stops and waits for a user to type something on the keyboard
print(variable)
```

Let us consider a more interesting example. A program will ask a user their name, and then will print it out.

```python
print("What is your name? ")
var_name = input()
print("Your name is: \%s" % var_name)
```

When Python executes the function input(), it
- stops the execution of the program
- shows a message on the screen
- waits for the user to type something and to press enter
- restarts the execution

NB! In Python 3 the message that the user sends to the program transforms into a string (note that an integer can also be considered as a string). For example, the following code will give an error:

```python
print("I will show you that I can multiply by two.")
var = input("Enter an integer: ")
var_double = var * 2
```

We can fix this error by converting the input into an integer using the function `int()`:  

```python
print("I will show you that I can multiply by two.")
var = int(input("Enter an integer: "))
var_double = int(var) * 2
```

If the input is a float, you can use the function `float()`.

You can check the type of a variable using function `type()`.

```python
var_1 = "tata yoyo"
print(type(var_1))
var_2 = 3
var_3 = 3.0
var_4 = input("Enter an integer: ")
var_5 = int(var_4)
var_6 = float(var_4)
```

**Exercise 0.** What are the types of the variables var_2, var_3, var_4, var_5 and var_6 in the example above? Check your answer using the function type().

**Exercise 1.** Write a program that asks a user their name, their age, and then prints “Next year [name] will be [age] years old”.

---

**Introduction to programming, lesson 2: Input / Output**
New type: Booleans

We have already seen three types of variables: strings, integers, floats. We will now introduce Booleans. A Boolean variable can take only two values: True and False. A Boolean expression is an expression that has value True or False. Here are some examples of Boolean expressions that use operators == ("is equal to"), != ("not equal to"), >, <, <= ("less or equal"), >= ("greater or equal").

```python
print(3 == 3)
p = 3 == 5
print(3 + 2 == 5)
p = 3 != 3
print(3 != 4)
p = 3 > 4
print(3 <= 4)
p = 3 <= 3
```

We can of course define a variable of Boolean type:

```python
var_bool_1 = True
var_bool_2 = False
print(var_bool_1, var_bool_2)
```

Conditional expressions : if / else

1. if statement

```python
if <condition>:
    #Four indented spaces!
    Steps to be executed if the condition is True
```

Try the following program first with a positive number, and then with a negative.

```python
var = int(input("Enter an integer: "))
if var > 0:
    print("The integer is positive")
```

Try to enter a float. What happens? How to fix it?

2. if … else statement

```python
if <condition>:
    Steps to be executed if the condition is True
else:
    Steps to be executed if the condition is False
```

Note that else is not followed by a condition. For example:

```python
var = int(input("Enter an integer: "))
if var > 0:
    print("The integer is positive")
else:
    print("The integer is negative or zero")
```

3. elif statement

```python
var_age = int(input("Your age: "))
if var_age < 0:
    print("You lie!")
elif var_age < 3:
    
```
print("You are a baby.")

elif var_age < 12:
    print("Go play outside!")
else:
    print("You have reasonable age.")

**Exercise 2.** Write a program that asks a user to enter two numbers \(a, b\), and then prints out “The sum equals \(a+b\)” if \(a+b\) is smaller than 100 and otherwise prints out “The sum is too large”.

### Boolean operators

#### The or operator

\((\text{expr}_1 \text{ or } \text{expr}_2)\) equals True if at least one of the two expressions \(\text{expr}_1, \text{expr}_2\) is equal to True. It equals False if both \(\text{expr}_1\) and \(\text{expr}_2\) are equal to False.

```python
var_age = int(input("What is your age? "))
if var_age <= 26 or var_age >= 60:
    print("You have a discount")
else:
    print("You pay the full price")
```

**Question:** for which values of \(\text{var}_\text{age}\) the expression \((\text{var}_\text{age} \leq 26 \text{ ou } \text{var}_\text{age} \geq 60)\) is equal to True?

#### The «and» operator

\((\text{expr}_1 \text{ and } \text{expr}_2)\) is equal to True if both \(\text{expr}_1\) and \(\text{expr}_2\) are equal to True.

```python
var_age = int(input("What is your age? "))
if var_age > 26 and var_age < 60:
    print("You pay the full price")
else:
    print("You have a discount")
```

**Question:** for which value of \(\text{var}_\text{age}\) the expression \((\text{var}_\text{age} \leq 26 \text{ and } \text{var}_\text{age} \geq 60)\) is equal to True?

### Some more exercises

**Exercise 1.** Write a program that asks a user to give a sequence of students as a string (e.g. “Alvaro Arenas, Roberto Bruno, Alexis Krauthgamer”), and creates a list of all students, a list of students whose family names start with letters A-M, and a list of students whose family names start with letters N-Z, and prints out the three lists.

**Exercise 2.** Write a program that asks a user to enter three integers, and outputs their maximum.

**Exercise 3.** A Hundred Thousand Billion Poems (original French title: *Cent mille milliards de poèmes*) is a book by Raymond Queneau, published in 1961. The book is a set of ten sonnets printed on card with each line on a separate strip. As all ten sonnets have not just the same rhyme scheme but the same rhyme sounds, any lines from a sonnet can be combined with any from the nine others, allowing for \(10^{14} = 100,000,000,000,000\) different poems. When Queneau ran into trouble creating the book, he solicited the help of a mathematician Francois Le Lionnais. Your task will be to write a script that generates a random poem from a similar book.

- Create a list of 5 lists, where each list corresponds to a group and contains 5 lines, i.e. strings (of your choice).
- Modify your script so that it returns a poem of 5 lines: line 1 is chosen from group 1, line 2 from group 2,..., and the number by each line is entered by a user from the keyboard.
